STUDIES IN THE DEVELOPMENT OF IMPROVED STRAINS OF PARASITES OF FOREST INSECTS

E 21 - FS - 7 FG - Po - 120 - 61

Report period: from January 1.1962 to December 31.1962.

annual negart ac. 2 .

CONFIDENTIAL

√50X1

CONFIDENTIAL

In the annual report No.1 the general problems and the attempt: to receive improved strains of various parasitic insects undertaken in past were discussed.

Such possibilities are studied in the reported period in case of Bahlboginus fuscipennis Zett. and Dirhichus ulbegunulatus Ratz., two parasitic hymenopterans attacking several forest insect peats.

As regards D.fugciponnig the studies on the level of bistic activity of several pure lines, that had been collected in different areas, have been completed. These studies showed that there is distinct differentiation of biotic activity in different atrains and that the most effective appeared to be the strains Nos.: VI, IX, XI, and without premise strains Nos.: V and VII.

It should be emphasized that copecially the focundity of pure lines inbred for 10 to 14 generations decreased very districtly. The crossing of several pure strains of D.fugcipennia was centinued.

As regards D. 21 boganulating the studies on langevity of the pure strains were completed. In this respect the mest effective appeared to be the strains Noc.: II and VIII. Until the present day the numbers of females of this parasite tested on biotic activity increased to 1500 and the general numbers of progeny obtained from these females increased to 70.000.

The general practical conclusions are: init is possible to obtain any required number of both studied species of parasites at any date.

- 2. the rewring of pure strains inbred for a long time is not ecoptable.
- In probably by crossing of lines with the positive features it would be possible to people's a ctruit with ideal features for use in biological central.

## Detailed Recert

### Introduction

In the period from 3.III. to 31.XII.1962 special interest was given to the D.fuzcipennig. The work on second species D.albo-annulatus was in beginning stage because the collecting of this parasite was possible in winter 1961-1962.

Studies made on pure lines of D.fuscipennis in the reported period showed that there is distinct differentiation of biotic activity in different strains.

It was found that the preseny of all crossed strike of both parasites is fertile.

The preliminary investigations on D. functionate showed that vitality of progray of crossed lines inreased in  $F_1$  and  $F_2$ .

As regards D.albegnylatus in several experiments it was found that this parasite had natural and unnatural insect hosts. As a basis for studies on biotic activity of this parasite the average quantitative relation between females and males, average fecundity of females, length of development of one generation, have been studied.

The several thousands cocoons of Diprion app. Gilpinia app. and pupae of Panolis flammes. Schiff. were callected in different areas as in the previous parieds.

The host-pupae were dissected in order to find the new pure strains of Do albumnulatus because during hibernation /1961-62 / . some studied pure strains of this parasite because exterminated.

Heat - cocoons and heat - pupae were segregated and then used for rearing of parasites, according to the same mexthods as in the past year.

The same concerned the criterions and motheds of rearing D. fuscipenis and D. albannulatus at the studies on biotic activity of seperate pure and crossed strains of both species of those parasites.

ை 3 ∞

## COnvidentales Reservines

In the reported period the characteristics of forest-biotops were made in which the seperate pure strains of D. alboannulatus and D. fuscipennis were collected. These characteristics made according to the rules applied in the forest studies concerned th following date: type of forest localieties, quality of soil, the stand, composition of stands, bottom etc.

As regarde D. fugcipennie the studies on pure lines of this parasite have been completed. The bistic activity of soparate pure strains is shown in the Table 1. The number of specimens tested in each of 11 strains was: 1000 of females on large vity, 500 of females and 1500 of cocoons on average number of parasitized thinn-walled coceens by I female, 600 of females and 600 of thick-walled cocoons on percentage of parasitization, 50 of females on searching capacity and 500 of females on fecundit The premissing value of each strain was characterized by a sum of points of all five studied features /Table 1/. The lowest number of points was assigned for the life longovity of females /11 points for the first place, 10 points for the second, etc./ the highest number of points for the average fecundity of females /15 points for the first place, 14 for the second, etc./. Such analysis of premissing value showed that most valuable strains are: VI, IX, XI and with low value are: V, VIII, X, VII.

In the preliminary studies on pure lines of this parasite the decrease of activity of pure lines inbred for about 4-5 generations was not observed. Therefore now the comparing of the average fecundity of 200 females from the generation 1 to 4 and of 200 females from the generations 10 to 14 showed that the fecundity of pure lines inbred for a long time decreased very distinctly /Table 2/.

During the reported period the crossing of several purstrains of D.fuscipennis was continued. The bistic activity of progeny received as results of cross-mating of various pure lines was studied. For example until the present day the number of females tested on longevity increased: strains I x III to 820, I x IX to 629, I x VI to 581, II x IX to 831 and strains III x to 809.

However because of unsufficient number of repetitions it is to early to indicate crossing of which pure lines will give the most prominent progeny.

As regards D. albeaunulatus during the reported period of our investigations studies on lengevity and focundity of pure lines were made.

The 1000 of females tested on longevity is each of the strain showed that there are the distinct differences between the average lengevity of one female in separate pure lines. / Table 3 /

Because of unsufficient number on femiles tested on fecundity and other criterions, it is difficult to say now which strains belong to the most offective ones.

The preliminary investigations on cross-breeding of different strains of D. alboannulatus showed that the progeny is fertile.

# Diseusaion

Although the studies made up to day on D. fuscipennic and D. albeanulatus are not complete it seems that seme of results are of important value for development of improved strains of these parasites.

It may be emphasized that the various strains from various areas differ significantly in biotic activity and only the offsetive ones can be recommended for biological control.

Besides, the activity of pure lines inbred for more than 10 generations decreased very distinctly. Although the crossing of pure lines inbred for a long time showed that biotic activity of their progeny has increased, whether this phenomen will disappear after some generations, will be found in the futere investigations based on the comparing of activity of crossed lines and pure lines.

Only by further selection and crossing of most positive lines it will be possible to obtain the improved strains.

Some difficulties have been stated during the studies on D.\_albeannulatus\_ Namely during the hibernation of the larval-stages of this parasite some of pure lines become exterminated. Therefore it is necessary to collect some new strains in the field and to begin the new investigations on them.

The special experiments to explain the conditions of hibernation of D. albeannulatus were established.

Another difficulty in our investigations is connected with the lack of sufficient number of pupes and cocoons. of host insects which didnot appear in mass number in Poland during reported period.

#### Comclusion

Based on the studies made on some points on biology and ecology of D. fuscipantis and D. albeanulatus the methods of mass rearing of those parasites were worked out.

Only the conditions of positive hibernation of D. albeanulatus are to be explained.

The completed investigations on pure strains of <u>D.fuscipennia</u> have shown the distinct differentiation in activity various lines. The most effective lines of this parasite are strains Nos. VI, IX, XI and they may be recommended for use in biological control of sawkies.

Apart of that the studies on pure lines that inbreeding for about 4-6 generations did not cause any decrease of biotis activity. However after 10-14 generations the activity of those lines, especially the fecundity of females, decreased very distinctly.

The cressing of several pure lines of both parasites was centinued. The studies on progeny of cross-mated strains of D. fuegigennis has indicated that it is possible to increase the biotic activity of parasite by this method. This last conclusion must be however, verified by additional experiments.

The plan the next year of our investigations includes compositing and starting of the fellowing problems:

- 1/ Completing of studies on bietic activity of pure lines of D. alboannulatum in order to find what strains are most effective.
- 2/ Completing of cressing of most active strains of D. fuscipenniz. Starting to cross the most active strains of D. albeannulatus. It must be also cleared by laboratory rearing of fow generations of parasite whether such positive features will be inherited or shall disappear as effect of heterozy.
- 3/ Obtaining in laboratory rearing of several theusands of purasites that will be used for preliminary introduction and checking of efficacy under matural conditions.
- 4/Collecting of few thousands of host-pupae and hestceccone for further laboratory rearing of both parasites.
